TOPOGRAPHY AND ULTRASTRUCTURE OF KIDNEY LYMPHATICS IN SOME HIBERNATING BATS

G. Azzali, G. Bucci, R. Gatti, G. Orlandini

Institute of Anatomy, School of Medicine, University of Parma, Parma, Italy

ABSTRACT

The kidney lymphatic system of some bats consists of intraparenchymal (interlobar, arcuate, and interlobular) and extraparenchymal vessels (capsular and prehilar connective). These vessels drain lymph via precollecting and prenodal collecting lymphatics into a hilar lymph node. There are no lymphatics in the renal medulla. The lymphatic vasculature (precollecting vessels excluded) is characterized by an endothelial wall lacking basal lamina and fenestrations. The endothelial cells, mostly rectangular in shape, are joined together by overlapping, end-to-end, and complex interdigitating junctions. Cytoplasmic expansions profile and thickness, intercellular junctions and particularly the different categories of uncoated vesicles (free or opened on luminal or abluminal surface) show qualitative and quantitative seasonal variations. Luminal and abluminal cytoplasmic processes appear (when analyzed in tridimensional reconstructions) as "intraendothelial channels." The increased number of these structures during summer characterizes them as dynamic elements and supports the concept of an active role played by them in transendothelial transport. Nevertheless, the main functional role is still ascribed (in addition to membrane transport mechanisms) to the vesicular system, also defined as the "vesicular route." We did not find any open intercellular junctions.

Despite many studies of the renal lymphatic system, uncertainty still exists regarding intra- and extraparenchymal peripheral absorbing vessel distribution as well as the legitimate role of tubular reabsorbate in lymph formation. Although previous studies based on dye or polymer injections permitted tridimensional reconstruction (1-5) and were useful to define morphologic interrelationships, they, nonetheless, left several issues unsettled: in particular the existence of lymphatics in the medulla and constituents of the nephron as well as the continuity between cortical and capsular vessels. Electron microscopy, and to a lesser extent, light microscopy (6-9), have to date only partially clarified the problem. In fact, as O'Morchoe exhaustively reports in a monograph (10), the existence of lymphatics in the cortex is unanimously accepted, but many disagree on the distribution in renal corpuscles and along the tubular system. Furthermore, there is no agreement about the existence (11-13) or absence (2,7) of medullary lymphatics. In fact, some physiological studies assert that the renal medulla contributes to renal hilum lymph formation (14,15). A recent study on dogs (16)

has described lymphatics among Henle loops and medullary ray collecting tubules at the cortico-medullary zone, but has failed to visualize them in the medulla. According to O'Morchoe (17), even if medullary lymphatics exist, their structural and functional role seems minimal in view of their rarity.

The aim of the present study was to assess renal lymphatic topography to augment Ottaviani's work (18) and to better define lymphatic ultrastructure in some species of bats in order to collect, through comparative topography and seasonal cytologic changes, useful data about lymphatic endothelial permeability particularly as related to trans-endothelial transport.

MATERIALS AND METHODS

Forty-six (46) adult bats (*Pipistrellus kuhli kuhli*, *Rhinolophus ferrum equinum*, and *Eptesicus serotinum*) were captured over several years (1980-86) in the provinces of Parma and Brescia. The bats were divided into 3 groups. The first group (18 bats) was captured and killed during the hibernation period (January and February); the second group (6 bats) was captured in the same season and kept in the laboratory for 2-3 days before killing. During this time they were not fed. The third group (22 bats) was captured during June, July, and August. Five of these bats had prenodal collecting lymphatics ligated for 5 hrs. A tridimensional mold of the renal lymphatic system was obtained in 6 bats (3 from the winter group and 3 from the summer group) by retrograde injection of Neoprene Latex 842/A (Du Pont) via a hilar node. Red and blue Neoprene were injected at the same time into the renal artery and vein, respectively, following the technique described by Ottaviani and Giacomelli (19). Furthermore, the lymphatic system of 3 bats (of the summer period) was visualized by retrograde injection of Prussian blue 15% in trementine oil.

The bats were anesthetized with sodium pentobarbital (Nembutal-Abbot). The kidneys were perfused through the aorta with tyrode solution and subsequently fixed with glutaraldehyde 3.5% in cacodylate buffer (pH 7.4) for 25 min. During perfusion, the latter solution was also dripped onto the renal surface as suggested by O'Morchoe and Albertine (20). Kidneys were excised and thereafter cut transversely to obtain small blocks of parenchyma (2-3mm). After 5 hrs wash in this buffer, the blocks were post-fixed by immersion with osmic acid in sodium cacodylate buffer (pH 7.4) for 2 hrs. After dehydration in acetone they were embedded in Durcupan. Sections 1μ thick stained with toluidine blue 1% in sodium carbonate 0.5% were analyzed to identify blood vessel bundles containing lymphatics and by a Reichert FM 90 microscope in order to center the lymphatic vessel and cut the specimens. Thin sections were stained with lead citrate according to Reynolds (21) and examined by a Phillips 300 electron microscope. Tridimensional reconstruction of several segments of endothelial wall (about 300μm in length) was carried out in 4 lymphatics (2 arcuate and 2 interlobular) by means of the wax-disk technique (22) recently revised by Werner (23). Furthermore, we analyzed 12 groups (240 serial sections each) of micrographs derived from 10 lymphatic vessels, 5 of them derived from bats killed during hibernation and the remaining from bats killed during the summer. From these micrographs the numerical densities, volume densities, and mean diameter for the different categories of the uncoated vesicles were determined by means of a Zeiss Videoplan image analyzer which was programmed to provide this information.

RESULTS

Light microscopy

Retrograde injection of Prussian blue and Neoprene Latex via a hilar

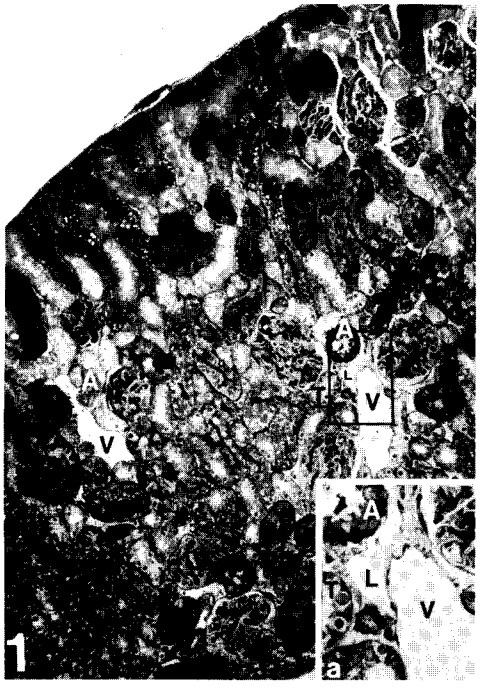

Fig. 1. R.f. equinum-*kidney-cortex. Two interlobular vascular bundles containing a lymphatic vessel (L) in the connective tissue (see also inset a) surrounding the artery (A) and the vein (V). A portion of the lymphatic endothelial wall borders the outer surface of a distal convoluted tubule (T). x150; x350.*

node shows mid-caliber intraparenchymal lymphatics (interlobar lymphatics). These vessels accompany interlobar arteries and veins and drain from the arcuate lymphatics lying at the outer limit of the outer medulla. Small-caliber lymphatic vessels arise from the same zone and then penetrate the renal cortex closely linked to interlobular blood vessels but never reaching the renal capsule. No lymphatics were detected in the renal medulla, but some were found in the renal capsule and the connective tissue interposed between cortical tissue and renal calyx. The lymph of these vessels drains via precollecting and prenodal collecting lymphatic into a single (sometimes double) hilar node.

This topographical distribution is confirmed by histological sections: lymphatics are uniformly present in the connective tissue encircling interlobar, arcuate and interlobular blood vessesl *(Figs. 1,2,4)*. It is important to emphasize that the lymphatic vessel encounters different relations along its course through the abundant connective

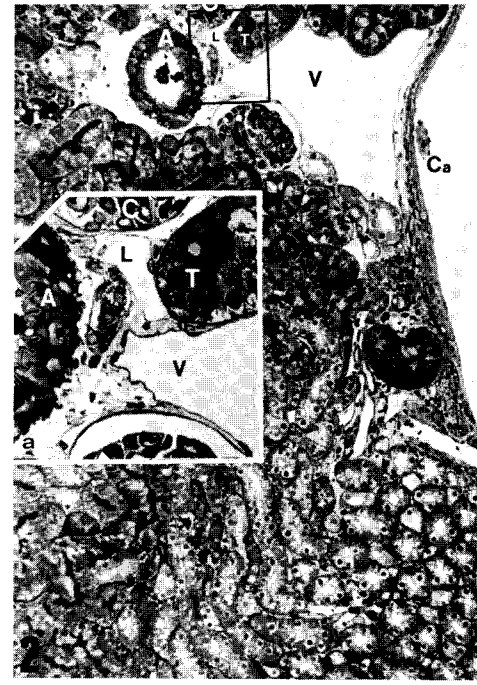

Fig. 2. P.k. kuhli-*kidney-cortex. At the top, vascular bundle at the limit between cortex and outer medulla: lymphatic (L) lies in the connective tissue between arcuate artery (A) and vein (V). tissue enwrapping the blood vessel bundle: sometimes it runs simply between the artery and the vein, whereas at other times a segment of the lymphatic touches the outer surface of a renal corpuscle, or the basement membrane of a proximal or distal convoluted tubule *(Figs. 1,2--insets a and 4)*. We did not observe lymphatics along the branch running from the interlobular artery to the renal corpuscle,

Fig. 3. **P.k. kuhli** *killed during the hibernating period-kidney-cortex. Lymphatic vessel (L) between interlobular artery (A) and vein (V). The endothelial wall is characterized by a linear profile and extremely thin segments of the cytoplasmic expansions (large arrows). Luminal and abluminal cytoplasmic membranes (of the above mentioned segments) are separated by a thin cytoplasmic layer without vesicles, RER and ribosomes (see also inset a and b). Intercellular junctions are of the overlapping and interdigitating type (small arrows). Luminal and abluminal vesicles are rare. x10,000; x27,500; x27,500.*

a finding also noted in other mammals (13,24).

Ultrastructure

Intra- and extraparenchymal lymphatic vessels, apart from diameter and seasonal cytological aspects, share common ultrastructural characteristics. Thus, they consist of a monolayer of flat endothelial cells lacking continuous basal lamina and fenestrations *(Figs. 3,6,8)*. The endothelial wall is formed by more cells, polyhedric or rectangular in shape, as demonstrated by tridimensional models built on serial thin sec-

tions. Each endothelial cell is characterized by: a) a quite bulky central part containing the nucleus and an abundant perinuclear cytoplasm containing Golgi apparatus, most rough endoplasmic reticulum (RER), mitochondria and some ribosomes; b) laminar and extensive cytoplasmic expansion where the peri-

pheral edges are joined to the neighboring cell by end-to-end, overlapping, and interdigitating junctions. One or more specialized junctional complexes (tight or gap junctions) are consistently present at the site of contact between two cells. These specialized junctional complexes occur with

different frequency in the three types of intercellular contacts. Tight and gap junctions occur together in the interdigitating intercellular contacts, whereas tight junctions are peculiar to the end-to-end and overlapping intercellular contacts. We observed slight accumulations of connective fibers in limited areas of abluminal plasma membrane outer surface.

Serial section analysis confirms the data of injection experiments of traditional substances. We noted a complete lack of continuity between interlobular and capsular lymphatics; moreover, in contrast to what was observed in the rat (25,26), we failed to visualize lymphatics related to the juxtaglomerular complex or to the afferent arteriole. Nonetheless, interlobular and arcuate lymphatics may abut (with a part of the endothelial wall) the outer surface of renal corpuscles or convoluted tubules (distal or proximal) and some collecting tubules.

Winter hibernation period

Intraparenchymal lymphatics are characterized by endothelial cells whose cytoplasmic expansions are laminar with a linear profile. Some areas of these expansions are slender (40nm) to such a point that luminal and abluminal plasma membranes are separated only by an extremely thin cytoplasmic layer in which free ribosomes are rare while vesicles, mitochondria, and RER tubules are absent *(Fig. 3 and insets a,b)*. The cytoplasmic expansion (except for the areas described above) is 110nm thick on the average and shows a clear cytoplasm containing free ribosomes, uncoated vesicles (60-70nm in diameter), and some mitochondria. Dense bodies and abluminal or luminal vesicles are rarely represented. The numerical densities, volume densities, and mean diameter for the different categories of uncoated vesicles (analysis performed on 5 lymphatic vessels) are shown in *Table 1*.

Table 1.
Hibernating

Vesicles	V_v $\mu m^3/\mu m^3$	N_v $\#/\mu m^3$	D nm
Abluminal	0.0006	3.6	60
Cytoplasmic	0.021	128	62
Luminal	0.002	12	60

V_v = volume density; N_v = numerical density; D = mean diameter

We classified as "luminal" or "abluminal" the vesicles which either touched or were continuous with the plasma membrane. "Cytoplasmic" vesicles appeared to be totally surrounded by endothelial cytoplasm in multiple serial sections (27). The cytoplasm surrounding the nucleus (with chromatin stacked in the peripheral karyoplasm) showed tubular RER, a poorly developed Golgi apparatus, some mitochondria presenting a clear matrix and some lysosomal dense bodies. The endothelial junctions were mainly of the overlapping and interdigitating type while end-to-end junctions were rare. The portions of the abluminal endothelial wall showing accumulations of collagenous fibers and dense connective ground substance were rare and limited in extent. Similarly, extraparenchymal lymphatics lying in the capsule and in the connective stroma between renal calyx and cortical tissue *(Figs. 6 and 7)*, except for precollecting lymphatics, showed an endothelial wall lacking continuous basal lamina. The endothelial cytoplasmic expansions had a linear profile, and luminal and abluminal vesicles were scarcely represented. Luminal and abluminal cytoplasmic processes which usually form intraendothelial channels were also rare.

Hibernating bats kept awake and not fed before killing

In this group, intraparenchymal and extraparenchymal lymphatics show a wavy endothelial wall almost without the slender areas described above. The

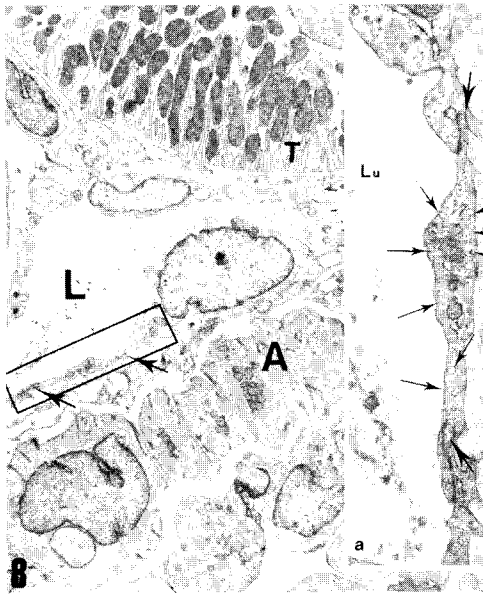

Fig. 8. P.K. kuhli *killed during the summer period-kidney-cortex. Lymphatic (L) between interlobular artery (A) and a distal convoluted tubule (T). The thick endothelial wall (see also inset a) is formed by more cells joined to each other by mainly interdigitating junctions (large arrows). The cytoplasmic matrix shows a rather well-developed RER, ribosomes and many luminal and abluminal vesicles (small arrows). Lu-lymphatic vessel lumen. x10,000; x27,000.*

intercellular junctions are mainly of the overlapping and interdigitating type *(Figs. 4 and 5)*. We did not observe open intercellular junctions. Frequently we observed luminal and abluminal cytoplasmic processes *(Fig. 5, inset a)* similar to those described by Niiro et al (9) in the hamster kidney endothelial wall. These morphological features correspond in thin section tridimensional reconstruction to the intra-endothelial channels previously described in the small intestine and urinary bladder (28-32). Perinuclear and cytoplasmic expansions present a clear matrix with RER tubules and micropinocytotic vesicles lying free or in relation to luminal and abluminal membranes. Quantitative analysis shows that the numerical densities, volume densities, and mean diameter of the uncoated luminal, abluminal, or cytoplasmic vesicles not to vary significantly when compared to that found during the hibernating period.

Summertime

Interlobular, arcuate, and interlobar vessels show a more winding endothelial wall in comparison to the previous seasonal aspects. Furthermore, the endothelium is thicker (230nm) and the intercellular junctions *(Fig. 8, large arrows)*, mainly overlapping, are fixed by gap and tight junctional complexes. We observed many luminal and abluminal cytoplasmic processes. The endothelial cell cytoplasmic expansions *(Fig. 8, inset a)* show a clear matrix particularly rich in ribosomes and uncoated vesicles (60-70nm). Rough vesicles are very rare. The free uncoated vesicles fill most of the cytoplasmic matrix and are often arranged in a chain-like manner across the endothelial surfaces. A large number of luminal and abluminal vesicles directly open on the lumen or the interstitium, respectively. These seasonal morphological differences are confirmed by an analysis of different groups of thin sections derived from 5 lymphatics. *Table 2* shows the numerical densities, volume densities, and mean diameter for the different categories of uncoated vesicles. The RER is well developed, and its tubules often look dilated. Numerous actin-like filaments are detectable in the abluminal peripheral cytoplasm. Dense lysosomal bodies are present in the perinuclear cytoplasm. Lipofuscin-like dense bodies

Luminal	0.007	28.5	68

V_v = volume density; N_v = numerical density; D = mean diameter

are rare. Ultrastructural features similar to those mentioned above are found in the endothelial wall of the extraparenchymal lymphatic vessels. Lymphatics lying in the renal capsule and connective tissue located between cortex and renal calyx continue as precollecting lymphatics. The latter show an endothelial wall containing a continuous basal lamina externally coated with a monolayer of smooth muscle cells, and continue as far as prenodal collecting lymphatics from which they differ in displaying more layers of smooth muscle. An almost identical ultrastructural pattern was observed during hibernation. Lymphatic stasis as a consequence of ligating a prenodal collecting lymphatic did not alter the ultrastructure in the lymphatic endothelium except for slight vessel dilatation.

DISCUSSION

These preparations show that the renal lymphatic vascular system of bats consists of intraparenchymal (interlobar, arcuate, and interlobular) and extraparenchymal (capsular and prehilar connective) vessels. Cortical lymphatics run adjacent to the blood vessels, as also described in dog and man (33-35), rat, hamster, rabbit (4,9,36,37), and pig (5). There are no lymphatic vessels in the renal medulla in agreement with previous observations in man and other mammals (36-39). Nevertheless, we find interlobular and arcuate lymphatics adjacent to renal corpuscles, convoluted tubules, and some collecting tubules as reported in rat and dog kidney (4,7,8). As far as the source of renal lymph production is concerned, our results suggest a perivascular (24,40,41) rather than a peritubular (9,40) origin. The lack of continuity between outer cortical and capsular lymphatics is in contrast to previous studies performed on other mammals (26,42) and particularly on other hibernating species such as the marmot and dormouse (Azzali, unpublished). This discrepancy may relate both to species-related differences and to the lack of connective tissue in the renal capsule.

As far as ultrastructure is concerned, intra- and extraparenchymal lymphatics, except for precollecting and prenodal collecting lymphatics, show an endothelial wall formed by monolayer flat cells lacking continuous basal lamina and fenestrations. The endothelial cells, rectangular in shape, are characterized by: a) a central body containing the nucleus which is surrounded by abundant cytoplasm containing ordinary cytoplasmic organelles; b) extended laminar cytoplasmic expansion whose peripheral edges are fixed to adjacent cell edges by end-to-end, overlapping, or interdigitating junctions. Thus these lymphatic vessels, as in other mammals (7,9,20), share common ultrastructural features (and as a consequence common functional features) which have been considered a peculiarity of the initial tract of the vessel (i.e., the capillary or initial lymphatic). Therefore, we suggest that the renal lymphatic vasculature exclusive of precollecting lymphatics and following vessels should be considered as part of the "absorbing lymphatic peripheral apparatus" (ALPA) (43,44).

The lymphatic endothelium also shows significant seasonal change. In fact, we found different qualitative and quantitative morphological ultrastructural features concerning the profile and thickness of both the cytoplasmic expansion and the intercellular junctions. Furthermore, cytoplasmic organelles, particularly the different categories of uncoated vesicles (60-70nm) show seasonal modifications. Thus, these vesicles (luminal and abluminal) are rare during hibernation whereas they are abundant in summer; they are often arranged in a chain-like fashion across the luminal and abluminal wall but without forming true intracellular channels. The higher numerical and volume densities concerning cytoplasmic vesicles observed in hibernation as

compared to summer probably relates to peculiar morphological aspects (e.g., expansion thickness) of hibernation itself. Our data are in agreement with previous observations performed on renal hilar lymphatics under experimental conditions of low temperature (45). Taken together the findings suggest that, in our biological model, the different transendothelial transport mechanisms are not consistent throughout the year. During hibernation in particular, active and/or passive membrane transport mechanisms may prevail over the "vesicular route" (44,46,47) and the intraendothelial channels which appear prominent in summer. We did not find any open intercellular junctions as described in dogs and pigs (3-5). The seasonal variations of the cytoplasmic expansion thickness and intercellular junctions represent a morphological expression of a functional picture (48,20) involving variable shifting of interstitial contents to lymphatic lumen. The endothelial wall shows luminal and abluminal cytoplasmic processes as described earlier in rats (4) and hamsters (9). These processes, analyzed by means of tridimensional reconstructions of serial thin sections, proved to be "intraendothelial channels" similar to those described in other organs (49-51). The dramatic increase of these structures during summer, as compared to their scarcity during hibernation suggests a dynamism whereby lymphatic endothelium can alter its internal structure (in response to still unknown physical or chemical factors) by virtue of endothelial cell high plasticity (52). In other words, the transendothelial transport mechanism possibly acts under particular conditions or need as a preferential pathway from interstitium to lymphatic lumen for fluids, solutes, and macromolecular aggregates. The foregoing ultrastructural changes of the lymphatic endothelium further suggest that the different metabolic and habitat conditions of hibernating mammals parallel the changes in renal lymph formation. A possible decrease in lymph formation during hibernation could, in accordance with Kayser (53), be ascribed to a sharp decrease in blood flow and, as a consequence, diminution in capillary filtrate.
